

Extended Essay — Physics

Title:

The Relationship Between Bluff Body Geometry and Vortex Shedding Frequency in a
Two-Dimensional Laminar Flow

RQ:

How does increasing the number of streamwise faces of a bluff body (ranging from 2 to 12) affect the vortex shedding frequency in laminar flow, measured in Hz, in a two-dimensional plane?

Word count:

1 Introduction

From the air we breathe to the water we consume; fluids are present in almost every aspect of our lives. Although observing fluids in action is a daily occurrence for all, countless remain unaware of the highly complex and intricate theories governing these seemingly simple and elementary phenomena. Ultimately, a profound youthful interest in cars and planes — everything with an engine really — coupled with a fascination for the motion of fluids led to the topic of this essay: vortex shedding. Specifically, this essay will concern itself with the question: *How does increasing the number of streamwise faces of a bluff body (ranging from 2 to 12) affect the vortex shedding frequency in laminar flow, measured in Hz, in a two-dimensional plane?*

Over the past century, vortex shedding has garnered a multifold of attention, with hundreds of papers published (Buresti, 1998, p. 61). This partially elucidated phenomenon is quintessential in a broad range of scientific and engineering contexts, from maintaining ubiquitous infrastructure to developing cutting-edge aerospace technologies. Bridges may suffer from vortex shedding excitation, a severe challenge which undermines their structural integrity (Jurado et al., 2012, p. 1040). This was exemplified by the collapse of the Tacoma Narrows Bridge on the 7th of November 1940, where vortex shedding acted as the instigating mechanism – triggering vertical vibration that eventually transitioned into the torsional oscillations, ultimately causing its collapse (Song et al., 2022).

Links can be made to Section C of the IB Physics Guide: *Wave Behavior* (“IB Physics Guide 2025”, 2023). Section C.1, *Simple Harmonic Motion*, concerns itself with an idealized theoretical representation of the behavior of oscillatory systems (Allum & Morris, 2023, p. 313). Fundamental concepts such as frequency and time period are discussed, ideas required in order to analyze the frequency of the vortex shedding caused by a bluff body. Furthermore, the topic of this essay also links to Section C.4, *Standing Waves and Resonance*. Concepts of natural frequency, vibrations and resonance are key when discussing the problems caused by vortex shedding.

2 Background

2.1 Frequency and Time Period

Frequency is defined as the number of occurrences of a periodic event per unit time (Allum & Morris, 2023, p. 78). **Time period** is referred to as the amount of time between each iteration of an event which happens periodically (Allum & Morris, 2023, p. 78). These two terms stand in an inverse relationship

$$f = \frac{1}{T} \quad (1)$$

where f is frequency in Hz and T is time period (s). This relationship is later utilized to extrapolate the vortex shedding frequency.

2.2 Fundamentals of Fluid Dynamics

Vorticity is the vector quantity representing the rotational motion in a velocity field (Holton, 2003, p. 2500). A **vortex** is the circular flow of a fluid around a central axis, characterized by the vorticity in the fluid (Nitsche, 2006, p. 390). A **bluff body** is defined as an object that, due to its geometry, induces significant regions of separated flow (National Research Council, 1997, p. 561).

A **Newtonian fluid** is a fluid in which the viscosity — a measure of internal friction — remains constant despite applied force. A **non-Newtonian** fluid exhibits a viscosity which varies with the applied force (Mohn, 2024).

Laminar flow is characterized by the layered motion of fluid particles, with no significant disturbance between the parallel layers (Versteeg & Malalasekera, 2007, pp. 40–41). On the other hand, **turbulent flow** is known to have continuous, irregular fluctuations in velocity and pressure throughout the fluid (Versteeg & Malalasekera, 2007, p. 40). A **compressible flow** is a flow in which the fluid does not have a uniform density (Oran & Boris, 2002, p. 31). Conversely, in an **incompressible flow** the fluid has a constant density (Versteeg & Malalasekera, 2007, p. 12).

The **Reynolds number** expresses the “ratio between inertial and viscous forces” (NASA Glenn Research Center, 2021). Given by the equation

$$\text{Re} = \frac{UL}{\nu} \quad (2)$$

where U is the free-stream velocity (m s^{-1}), L is the characteristic length (m), and ν is the kinematic viscosity ($\text{m}^2 \text{s}^{-1}$) (“The Relationship Between Reynolds Number and Kinematic Viscosity”, n.d.). This number allows one to classify whether a flow is laminar or turbulent, with low Reynolds numbers signifying laminar flow and high Reynolds numbers indicating turbulent flow, though the exact threshold values vary between sources (Saldana et al., 2024).

The **Strouhal number** is a dimensionless parameter used to describe the periodicity of vortex shedding (Choi & Kwon, 2000, p. 211). It is given by the equation

$$\text{St} = \frac{fL}{U} \quad (3)$$

where f is the frequency of vortex shedding (Hz), L is the characteristic length (m), and U is the free-stream velocity (m s^{-1}). A high Strouhal number — assuming both L and U remain constant — indicates an increased f , conversely a low Strouhal number indicates a lower f . Both the dimensions and geometry of the bluff body impacts the Strouhal number, and therefore the vortex shedding frequency (Ibrahim, 2022, p. 32).

This essay will analyze vortex shedding in a Newtonian fluid — water — which exhibits laminar and incompressible flow. A Reynolds number of 100 was targeted in order to ensure laminar flow with periodic vortex shedding (Alammar, n.d. p. 2); however, due to practical limitations, this was only fully realized theoretically and not in practice. Given the very limited research in three-dimensional vortex shedding (Buresti, 1998, p. 63), this paper concerns itself with vortex shedding in two dimensions. While the simulation was conducted in a two-dimensional domain, the practical experiment could only approximate two-dimensional flow.

2.3 Vortex Shedding and the Kármán Vortex Street

Vortex shedding in a two-dimensional plane can be defined as the phenomenon in which localized regions of high vorticity are periodically released into the wake from alternating sides of a bluff body, each exhibiting an opposite rotational direction (Green, 1995, p. 156). The Kármán Vortex Street refers to the distinct flow pattern created, a repeated structure of counter-rotating vortices (Govardhan & Ramesh, 2005, p. 26).

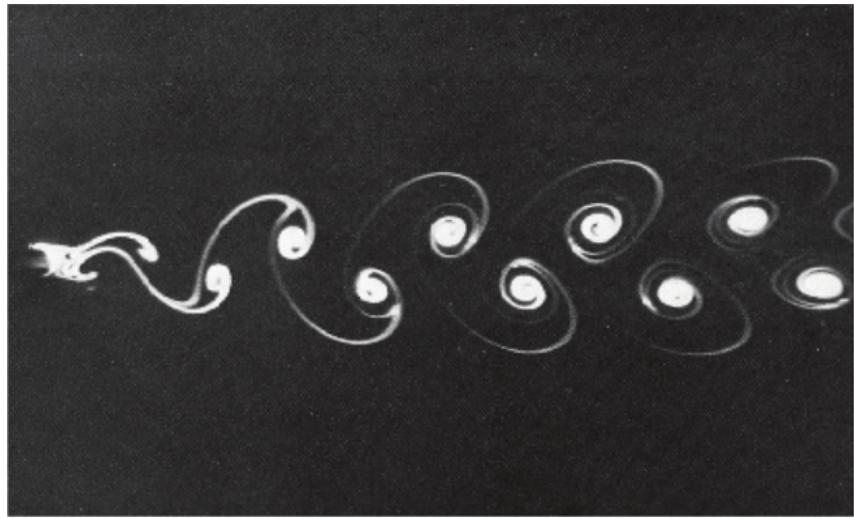

Figure 1: Von Kármán Street behind a cylinder in a non-rotating 2D flow for $Re = 140$, fluorescein visualization (Ilieva, 2017, p. 144)

2.4 The Mechanism of Vortex Shedding

Due to the friction between a given fluid and a bluff body, there is no relative motion between them (Jeff Defoe, 2020; TutorialsPoint, 2018). Consequently, if the velocity of the bluff body is zero, the velocity of the fluid at the wall of the bluff body, with respect to the reference frame of the bluff body, is also zero: a no-slip condition. This causes a variation in velocities with distance, from zero at the bluff body surface to the free stream velocity U at a certain distance from the bluff body. The region in which this velocity gradient occurs is referred to as the boundary layer.

Distance

from

bluff body,

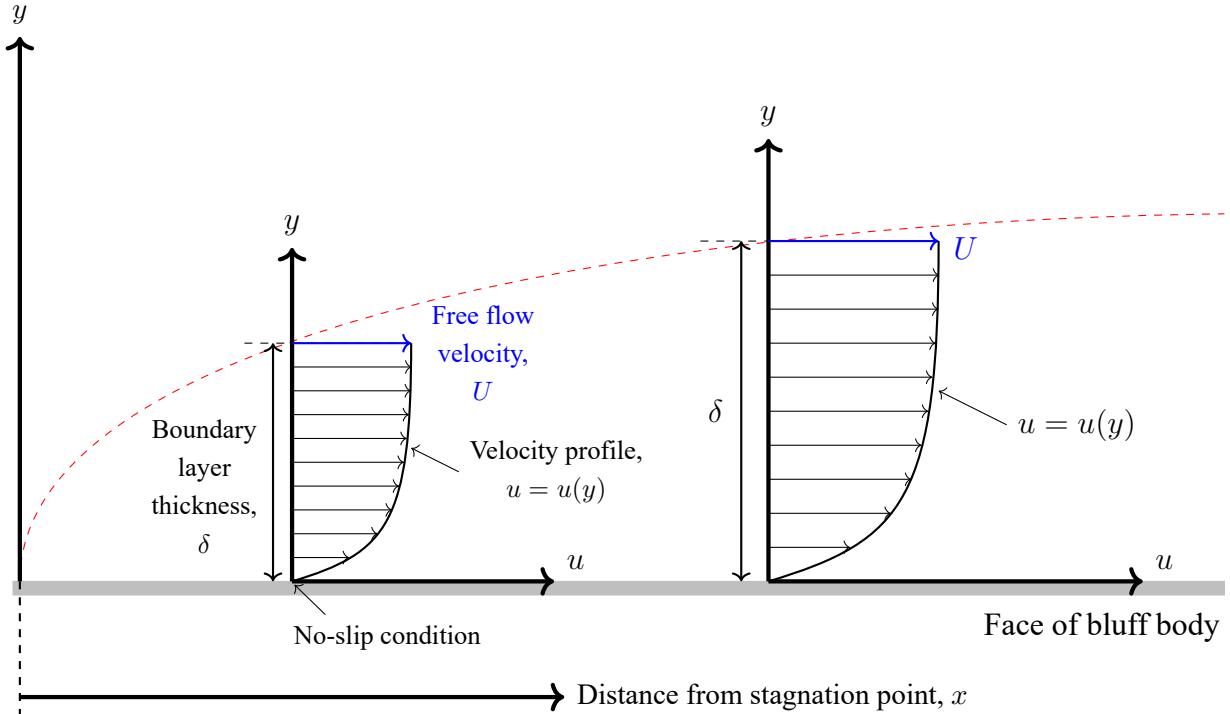

Figure 2: Depiction of boundary layer and the velocity gradient formed. The red dotted line depicts the outline of the boundary layer. Inspired by Embry-Riddle Aeronautical University (n.d.).

When a flow moves past a bluff body in a two-dimensional plane, a boundary layer develops, with increasing thickness δ from the *stagnation point* (Fitzpatrick, 2016) — the point on the leading edge of the bluff body at which the local fluid velocity is zero (with respect to the bluff body) — to the back of the bluff body (Learn Engineering, 2022).

At a certain point, the boundary layer separates from the bluff body, forming a shear layer. Under steady flow conditions, this separation occurs in a periodic and alternating manner, creating two separate, out-of-phase shear layers on either side of the bluff body.

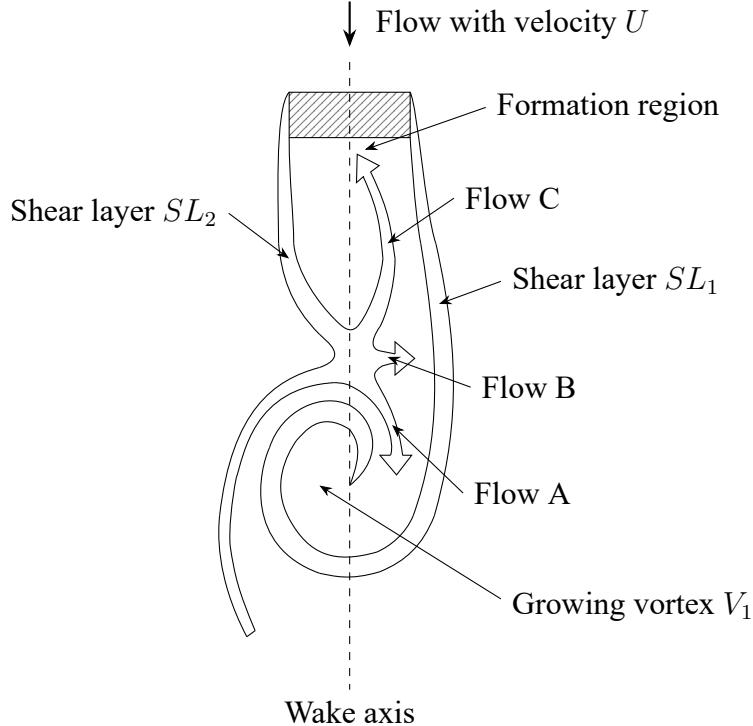

Figure 3: The mechanism of vortex shedding. Inspired by Shen et al. (2010, p. 3)

For simplification, assume the first shear layer is generated at the right of the bluff body (SL_1). Due to its vorticity, the shear layer tends to curl up, forming a vortex. As the vortex forms, the pressure in the core of the vortex decreases, acting as a sink, inducing inflow towards its center. The fluid initially present at the backside of the bluff body is drawn into the vortex, creating space, allowing for the formation of the left shear layer (SL_2) in the *formation region*. This newly created shear layer splits into three distinct flows: a flow (*Flow C*) which recirculates behind the bluff body, a flow (*Flow B*) which mixes with the right shear layer (SL_1) and a flow (*Flow A*) which is drawn into the vortex (V_1).

There is a decrease in strength of the vortex being created due to *Flow A* having an opposite vorticity to the vorticity of the vortex. Moreover, the opposite vorticity of *Flow B* and the right shear layer effectively nullifies each other, leading to the right shear layer being interrupted and the vortex becoming detached, causing it to travel with the main flow. The vortex has been “shed”. Since the vortex moves away from the bluff body, its low-pressure influence on the area near the bluff body decreases, allowing the left shear layer to develop more freely. Now, due to the periodic nature of vortex formation, the process recurs with the shear layers switching roles.

When considering the vortex being created from the right shear layer (SL_1), the fluid on the right of the vortex will have the same velocity as the free stream velocity U , whereas the velocity on the left of the vortex will be of a smaller magnitude and in the opposite direction of the main flow. According to Bernoulli's equation, a region of higher velocity must have a lower pressure and vice versa. Therefore, the left region of the vortex will have a higher pressure than the right region, causing a lift force which acts on the bluff body normal to the flow. The oscillation of this lift force coincides with the vortex shedding frequency f .

2.5 Hypothesis

It was hypothesized that as the number of streamwise faces of the bluff body increases from 2 to 12, the vortex shedding frequency in laminar flow will decrease. This trend is attributed to a decrease in the Strouhal number — as shown by Gonçalves and Del Rio Vieira (1999) — which is directly proportional to the vortex shedding frequency (see Equation (3)).

3 Variables

Independent Variable	Number of streamwise faces n of the bluff body (ranging from 2 to 12)
Dependent Variable	The vortex shedding frequency (Hz)
Constant Variables (Theoretical Investigation)	<ul style="list-style-type: none"> – Overall length of bluff body i.e. the characteristic length (m) – Simulation settings (detailed in Section 5.2.3) – Fluid domain dimensions (m) – Mesh resolution (m)
Constant Variables (Practical Investigation)	<ul style="list-style-type: none"> – Overall length of bluff body i.e. the characteristic length (m) – Fluid used (water) – Water temperature ($^{\circ}$C) – Flow velocity (m s^{-1}) – Position of bluff body – Lighting conditions – Camera setup and settings – Measurement duration (min) – Material and surface finish of bluff bodies

5 Method

5.1 The Bluff Body

In order to maintain a cylinder-like appearance, one of the most common bluff bodies investigated (Rocchi & Zasso, 2002, p. 475), this investigation used bluff bodies featuring a rectangular “tail”. This results in each bluff body having an overall length ℓ in both streamwise and transverse directions — analogous to a cylinder. The characteristic length L of each bluff body is therefore equal to the overall length ℓ . Bluff bodies with streamwise faces n ranging from 2 to 12 were investigated. The lengths of the n faces within the bluff body n were homogeneous. A square bluff body ($n = 1$) was excluded due to its fundamentally different flow interaction attributed to the lack of multiple streamwise faces. As the practical investigation occurs in three dimensions, each bluff body was constructed with a fixed height, approximating the two-dimensional behavior observed in the simulation (see Figure 12).

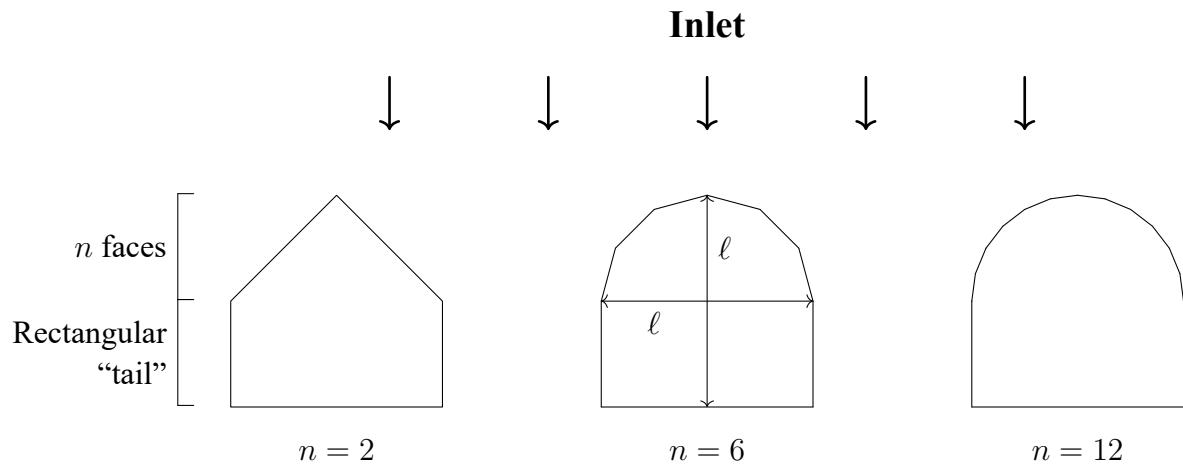

Figure 4: Examples of the bluff bodies

5.2 The Theoretical Investigation

5.2.1 Ansys Workbench

The geometry and mesh preparation for the simulation was conducted using Ansys Workbench (“Ansys Workbench | Simulation Integration Platform”, n.d.). The dimensions of the fluid domain are based on Figure 5 where ℓ is the overall length of the bluff body.

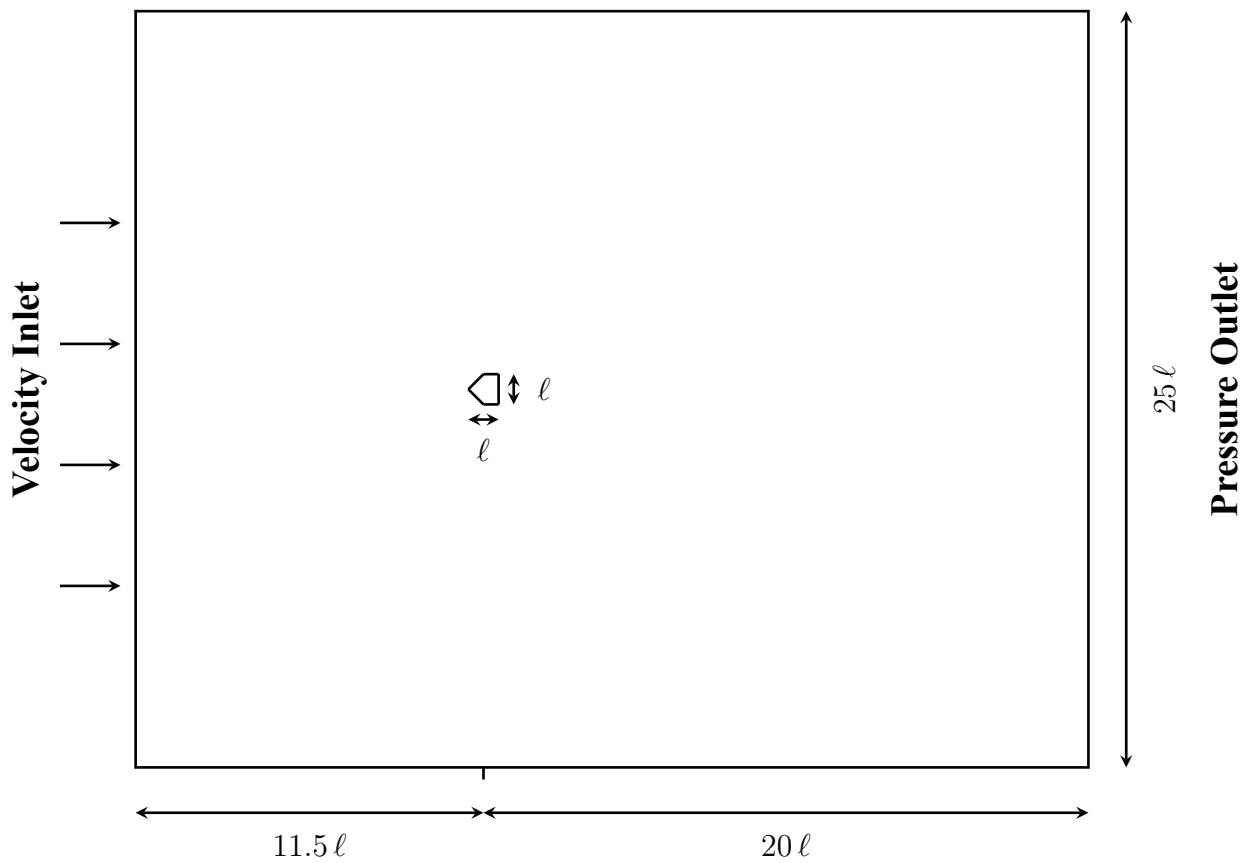

Figure 5: The fluid domain with dimensions. Example with bluff body $n = 2$. Inspired by comflics (2014)

Given the computational limitations of the computer the simulation was conducted on, $\ell = 1 \times 10^{-3}$ m was chosen — therefore $L = 1 \times 10^{-3}$ m.

In order to create the mesh necessary for the simulation, the *All Triangles Method* was utilized. A global unit size of 2.25×10^{-3} m was applied to the fluid domain to ensure a computationally inexpensive resolution in regions of negligible interest. Conversely, near the edge of the bluff body, a significantly smaller unit size of 2.0×10^{-5} m was used, constituting an

accurate depiction of the interaction between the fluid flow and the bluff body (Ansys Learning, 2023). Furthermore, eight inflation layers were employed in order to precisely capture the gradients associated with boundary layer formation at the edges of the bluff body (Fluid Mechanics 101, 2021). Moreover, a body of influence (BOI) with a sizing of 2.0×10^{-4} m was used — positioned as shown in Figure 6 — refining the mesh around the bluff body and also in the wake region (where the vortex shedding occurs), constituting for a more exact simulation.

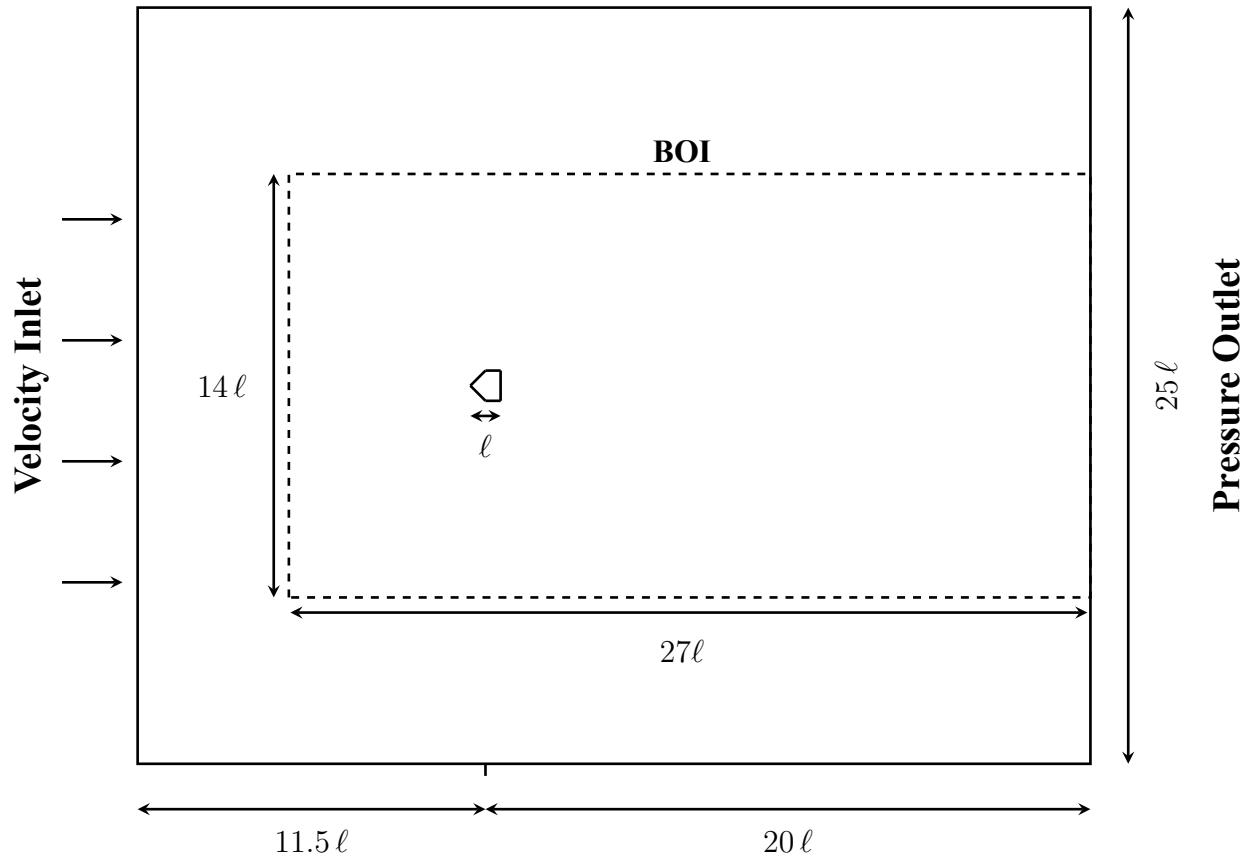

Figure 6: The fluid domain with dimensions and the BOI. Example with bluff body $n = 2$. Inspired by comflics (2014)

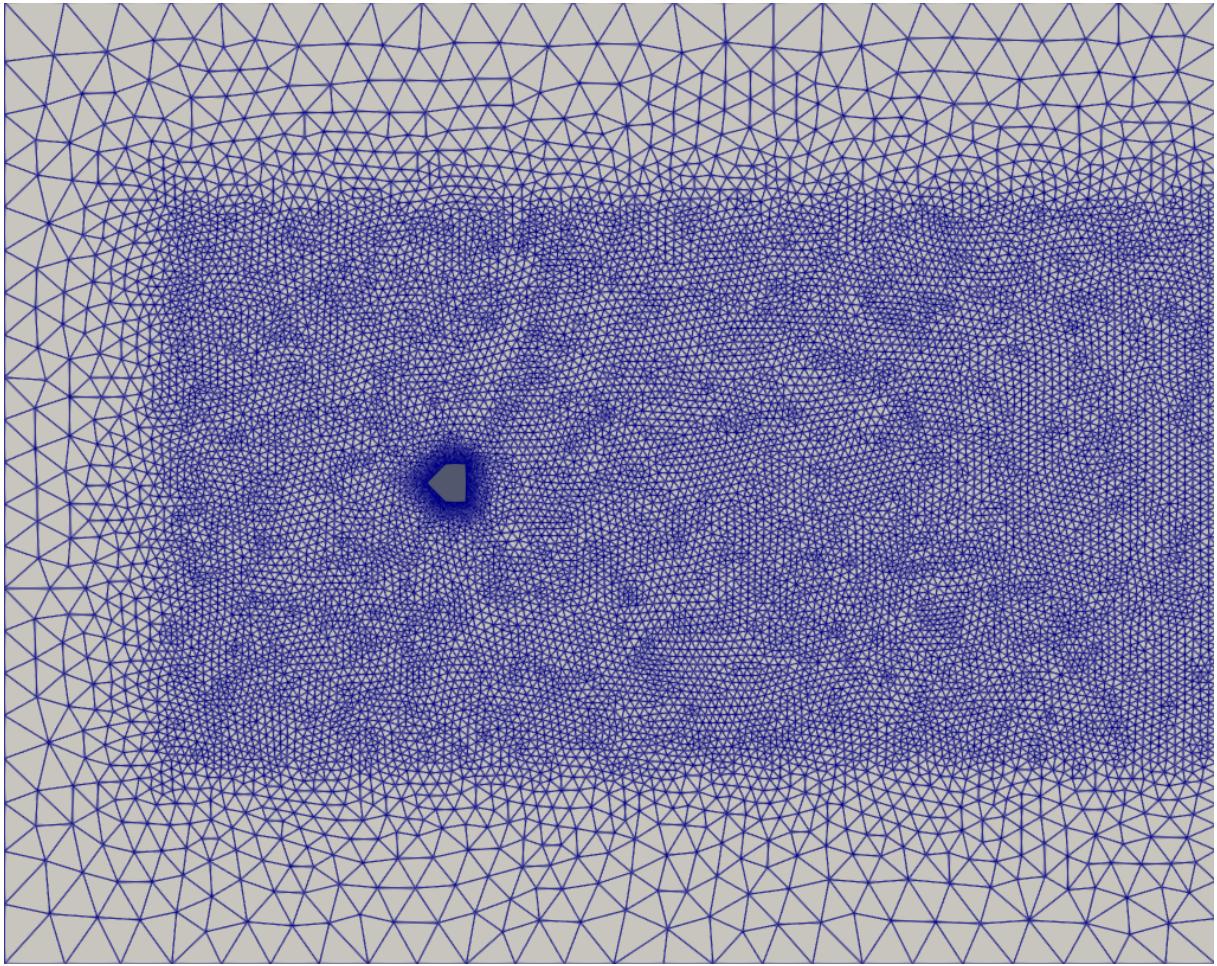

Figure 7: Example of mesh of fluid domain with bluff body $n = 2$. Visualized in ParaView.

5.2.2 The OpenFOAM Simulation

The theoretical part of this EE was conducted using the open-source CFD software package OpenFOAM (“OpenFOAM”, 2024) in Windows Subsystem for Linux (WSL) (“Windows Subsystem for Linux (WSL)”, n.d.). Among the numerous solvers OpenFOAM provides, pimple-FOAM is a transient, pressure-based solver for incompressible, single-phase flows (“pimple-Foam - OpenFOAM Solver - SimFlow CFD Software”, n.d.). It facilitates robust handling of transient simulations with larger time steps, allowing for improved computational performance. Moreover, its ability to model both laminar and turbulent flow ensures flow conditions are accurately reflected and given that the fluctuations of lift force in laminar flow are sinusoidal, one can verify the flow is laminar. Utilizing reporting functions, one can extract the lift coefficient C_L , which shows the fluctuations in the lift force acting on the bluff body.

5.2.3 Simulation Settings

To adhere to the scope of this essay, the simulation setup was adapted from a case study provided in the Udemy course *OpenFOAM for Absolute Beginners* by Jayaraj P (2024). The tutorial case *3vortexShedding*, discussed in lecture eight, served as a structural template and was modified to align with the specific requirements of this investigation.

5.3 The Practical Investigation

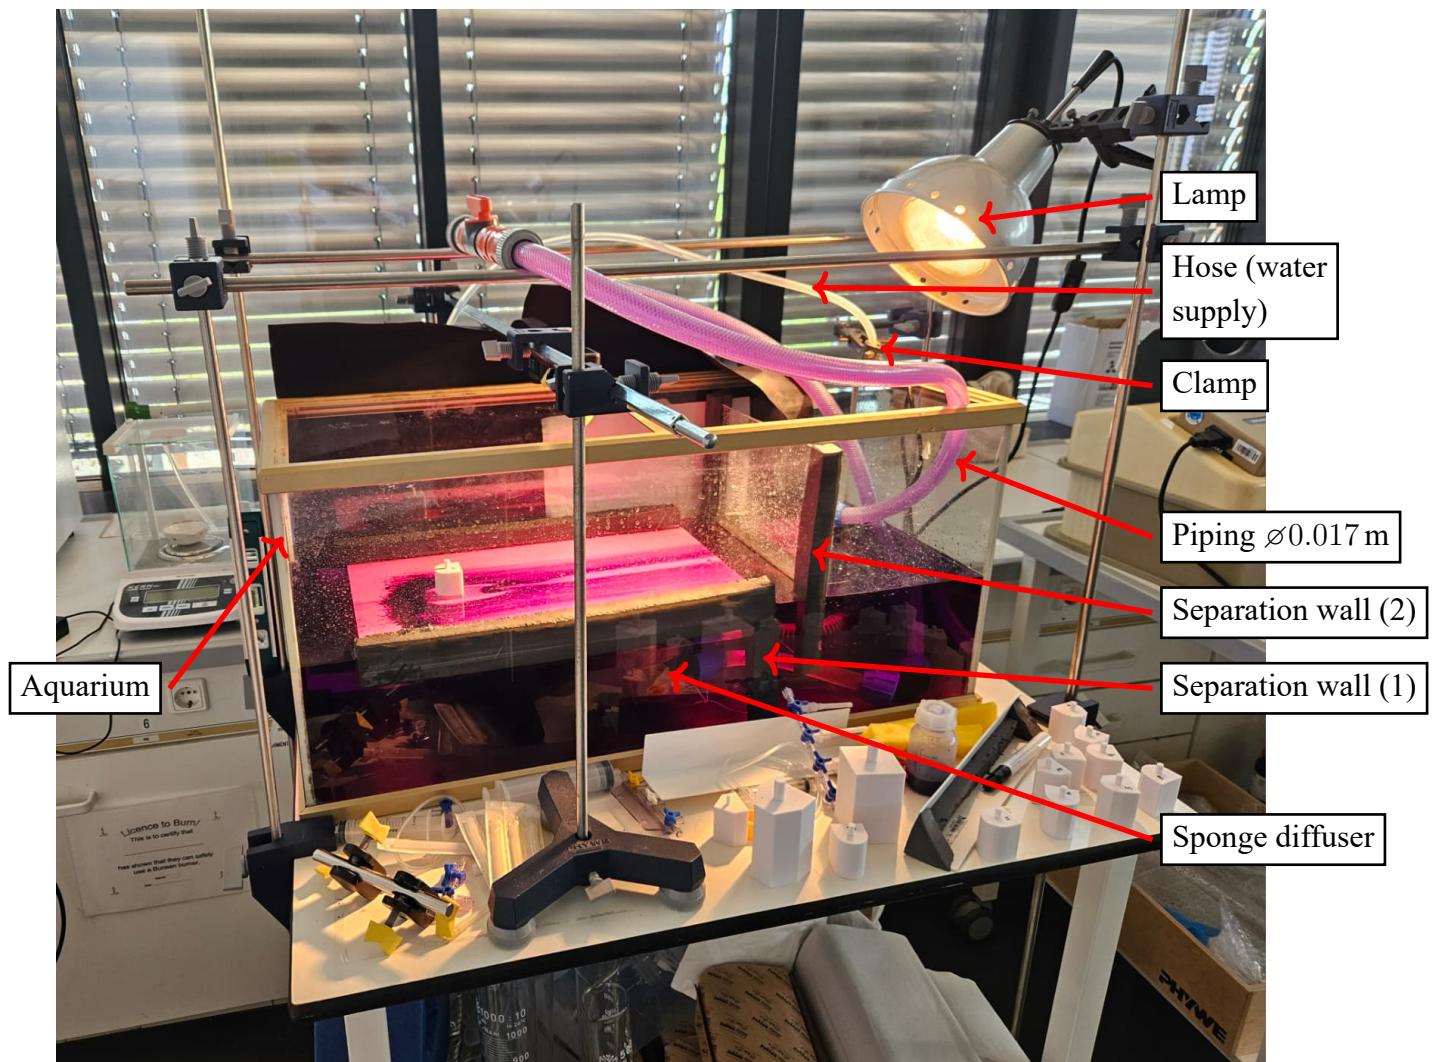

Figure 9: The setup for the practical investigation (angle 1)

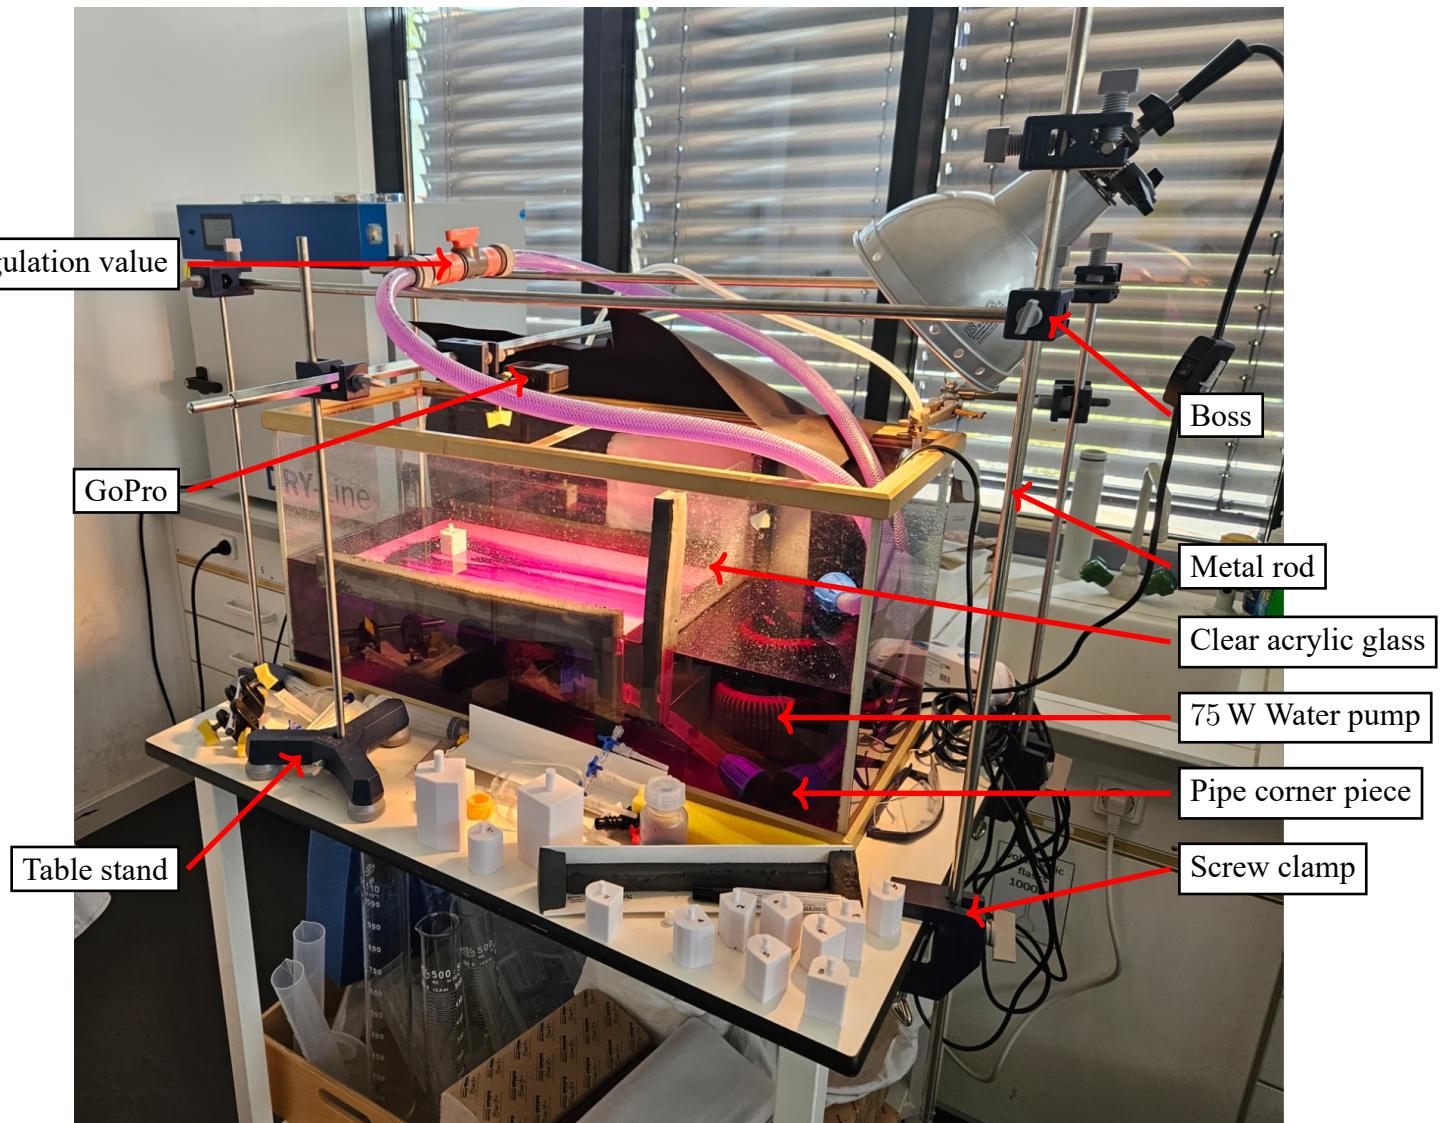

Figure 10: The setup for the practical investigation (angle 2)

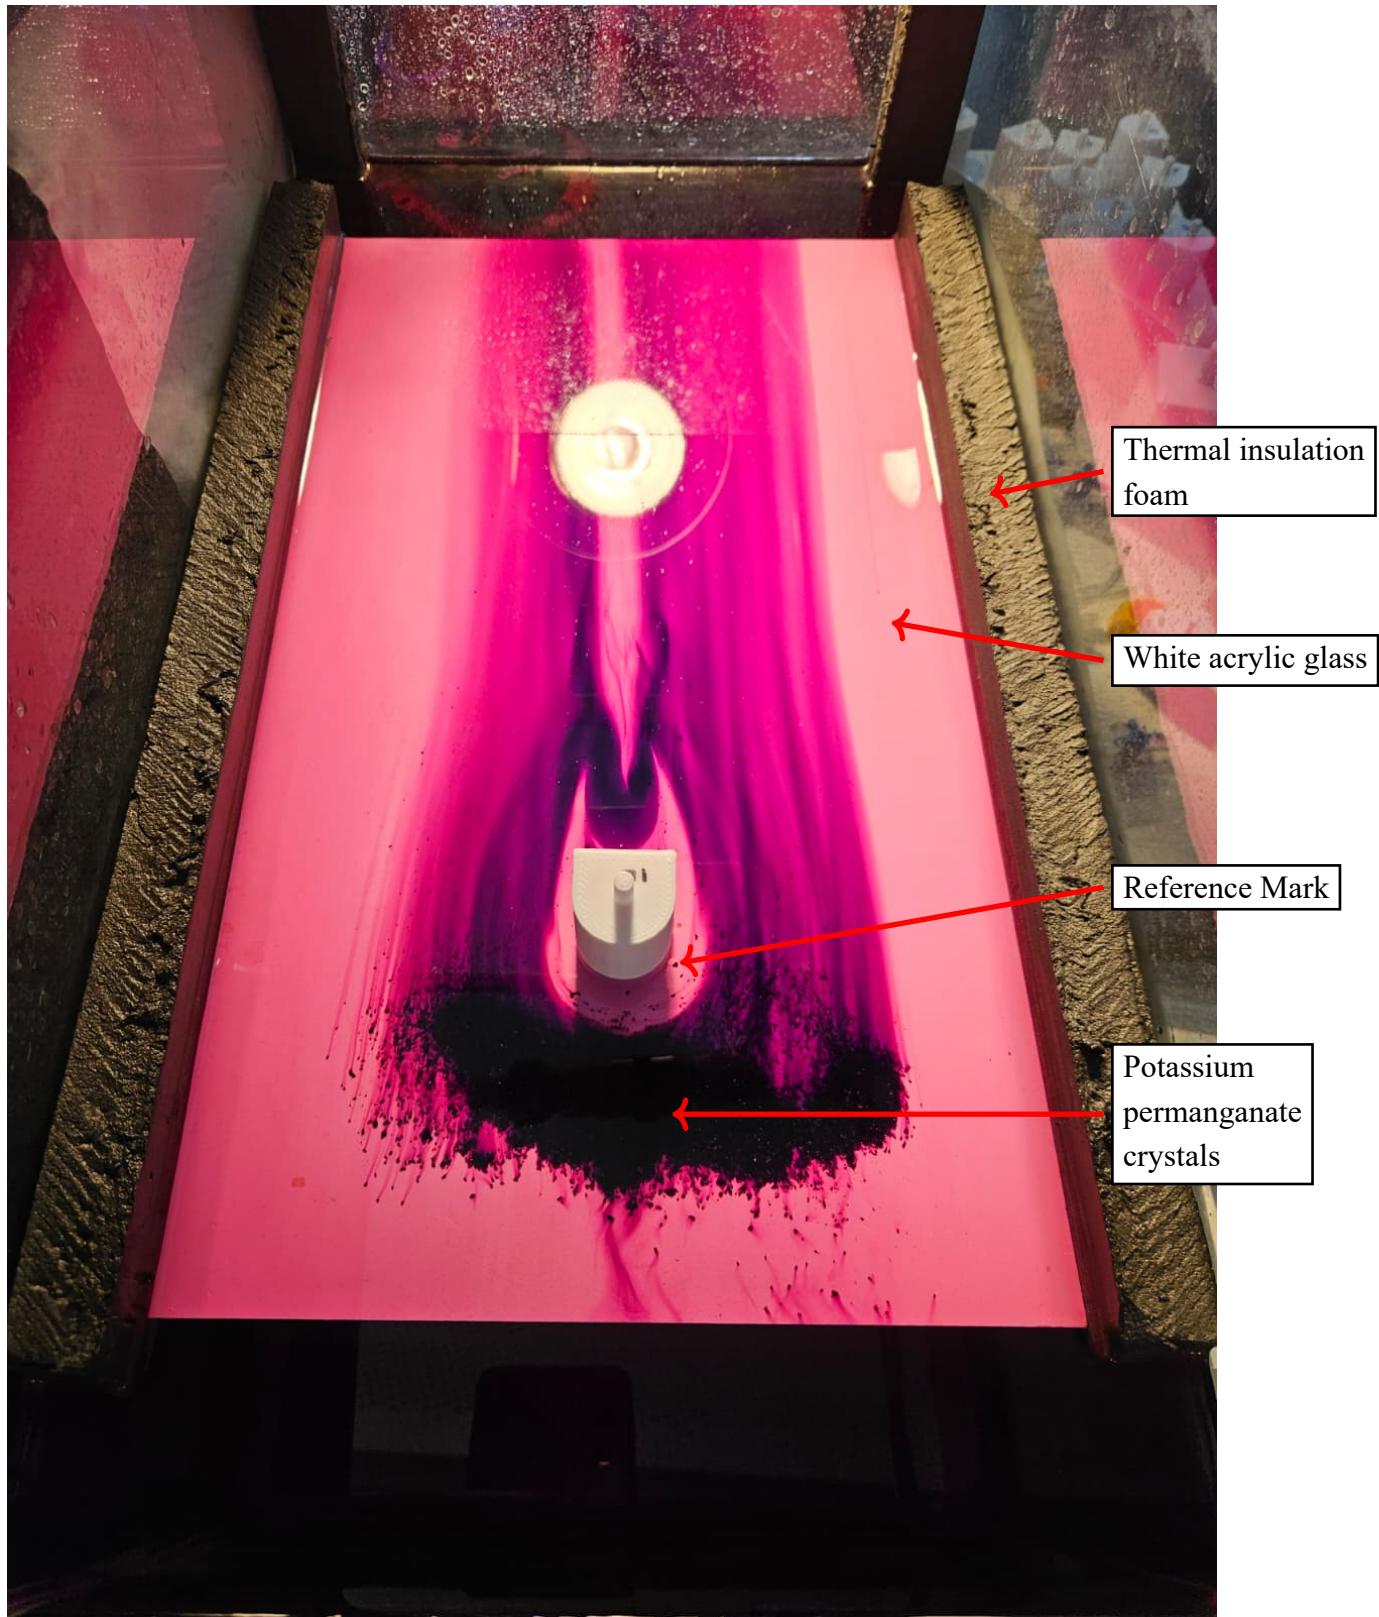

Figure 11: A bluff body positioned in the flow tank with potassium permanganate crystals spread in front of it

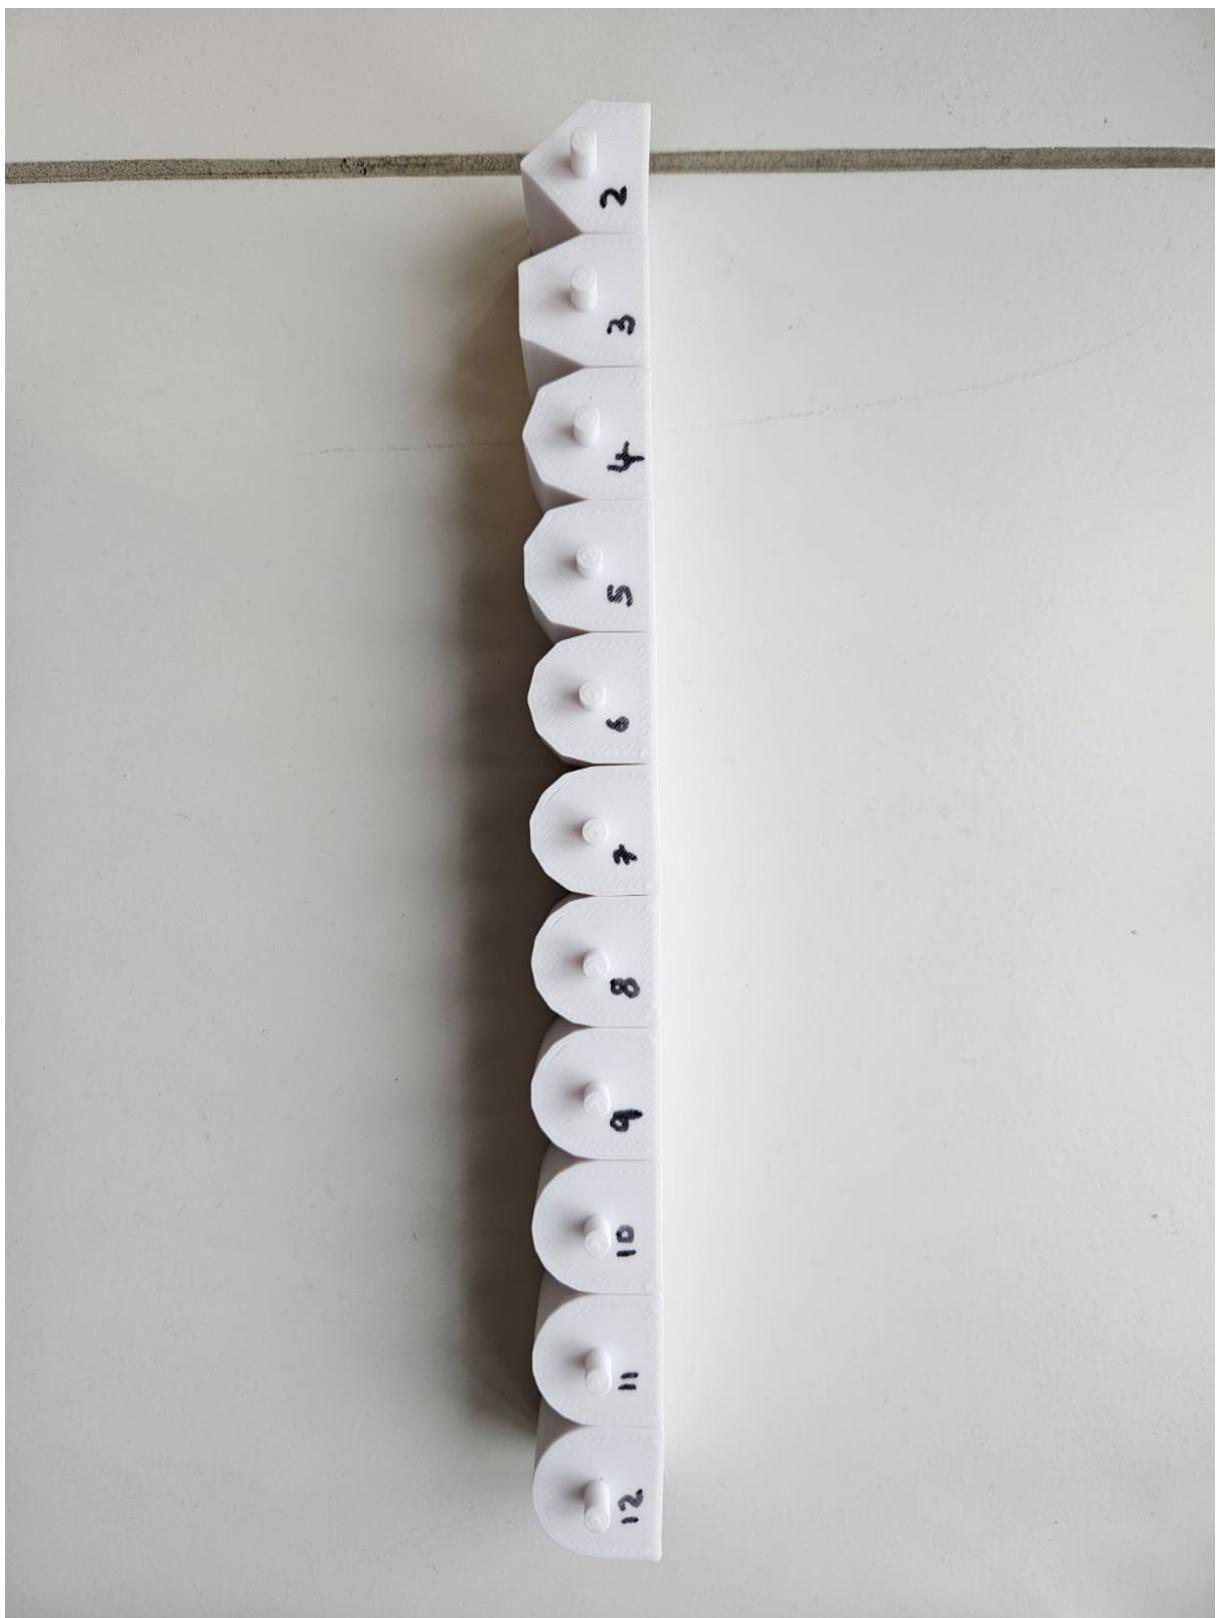

Figure 12: The 3D-printed bluff bodies of fixed height. The numbers correspond to the number of inlet-facing sides

Inspired by the flow tank built by Harvard University’s Science Demonstrations Center (“Vortex Shedding in Water | Harvard Natural Sciences Lecture Demonstrations”, n.d.), the practical part of this EE was conducted in a self-built flow tank. A water pump created a flow over a horizontal plate by moving water from one side of separation wall (1) to the other. Separation wall (2), which did not reach the bottom of the tank, forced the flow of the horizontal wall towards the pump. The aquarium was filled with water so that it reached 0.01 m above the horizontal plate. The regulation valve was used to decrease the flow velocity while the sponge diffuser ensured a uniform distribution of flow — in an attempt to achieve laminar flow. Both a lamp and the addition of potassium permanganate crystals in front of the shape were used in order to better visualize the water flow. The thermal insulation foam ensured watertightness between the aquarium wall and the inside components.

The bluff bodies were 3D printed with an overall length ℓ of 0.02 m — giving each shape a characteristic length L of 0.02 m — and a height of 0.04 m. Pre-tests showed that this overall length proved to be the optimal balance between the size of the bluff bodies and adequate identification of produced vortices, in an attempt to achieve a Reynolds number of 100. Reference marks on the horizontal plate ensured the shape was positioned consistently each trial. A GoPro recording in 120 FPS was mounted parallel to the horizontal plate, ensuring a continuous recording of the entire horizontal plate. The outer scaffolding provided support for the lamp, the GoPro and the water supply hose.

The flow velocity for the subsequent calculation of the Reynolds number was measured using a basic time-distance method, wherein a float was introduced and the time taken to travel the length of the horizontal plate was measured via a digital stopwatch. This was repeated ten times and an average was taken.

5.4 Determining the vortex shedding frequency

The inverse relationship given by Equation (1) will be used to determine the vortex shedding frequency. By measuring the time interval between the formation of two consecutive vortices on one side of the bluff body, one can find the time period and therefore the frequency of vortex shedding. To obtain an accurate vortex shedding frequency, the determination of the time period

was completed after periodic vortex shedding was achieved, omitting the initial startup phase in which the flow developed. A Fast Fourier Transform approach was not chosen due to the lack of sufficient runtime during the trials on either investigation and the absence of multiple different frequencies of vortex shedding (Shi et al., 2025, pp. 10–11; Xu et al., 2025, p. 12).

5.4.1 Theoretical Investigation

The simulation was run five times for each bluff body. It was found that each iteration of a bluff body yielded the same results, therefore only the first run of each bluff body was considered. By graphing fluctuations of the lift coefficient (see Section 6.1.2), one can calculate the time period of vortex shedding by identifying the time taken between two consecutive peaks or troughs. This determination was done for each peak and trough using Python — see Appendix A — removing the first second to omit the startup phase. An average time period was then calculated and the vortex shedding frequency was found. ParaView was used to visualize the simulation.

5.4.2 Practical Investigation

The bluff bodies were placed into the flow tank at the position of the reference marks. Wearing gloves and goggles, minimal amounts of potassium permanganate were placed in front of them using a spatula — as shown in Figure 11. Once the flow fully developed, it was recorded for one minute each time. This minimized the number of water replacements — due to dissolving potassium permanganate turning the water purple — while ensuring that one could take multiple measurements of the time period. The water was reused for four shapes before the aquarium was emptied using a hand pump — disposing the solution in a properly assigned waste tank — and was refilled with fresh water.

The time period of vortex shedding was found via visual inspection of the GoPro footage and using a digital stop watch. It was repeated ten times for each bluff body. An average was subsequently calculated and the vortex shedding frequency was determined.

6 Results

6.1 Results of the Theoretical Investigation

6.1.1 Sample Table of Time vs. Lift Coefficient (C_L) for Bluff Body $n = 2$

Time (s)	C_L
1×10^{-5}	$2.0946206 \times 10^{-11}$
2×10^{-5}	$-6.5426717 \times 10^{-12}$
3×10^{-5}	$-7.3241302 \times 10^{-12}$
4×10^{-5}	$-6.6677951 \times 10^{-12}$
5×10^{-5}	$-5.1304516 \times 10^{-12}$
6×10^{-5}	$-4.3635501 \times 10^{-12}$
7×10^{-5}	$-3.6837751 \times 10^{-12}$
8×10^{-5}	$-3.2635206 \times 10^{-12}$
9×10^{-5}	$-2.8660898 \times 10^{-12}$

Only a representative sample is shown here for clarity. Complete datasets available on request.

6.1.2 Lift Coefficient (C_L) Over Time for each Bluff Body

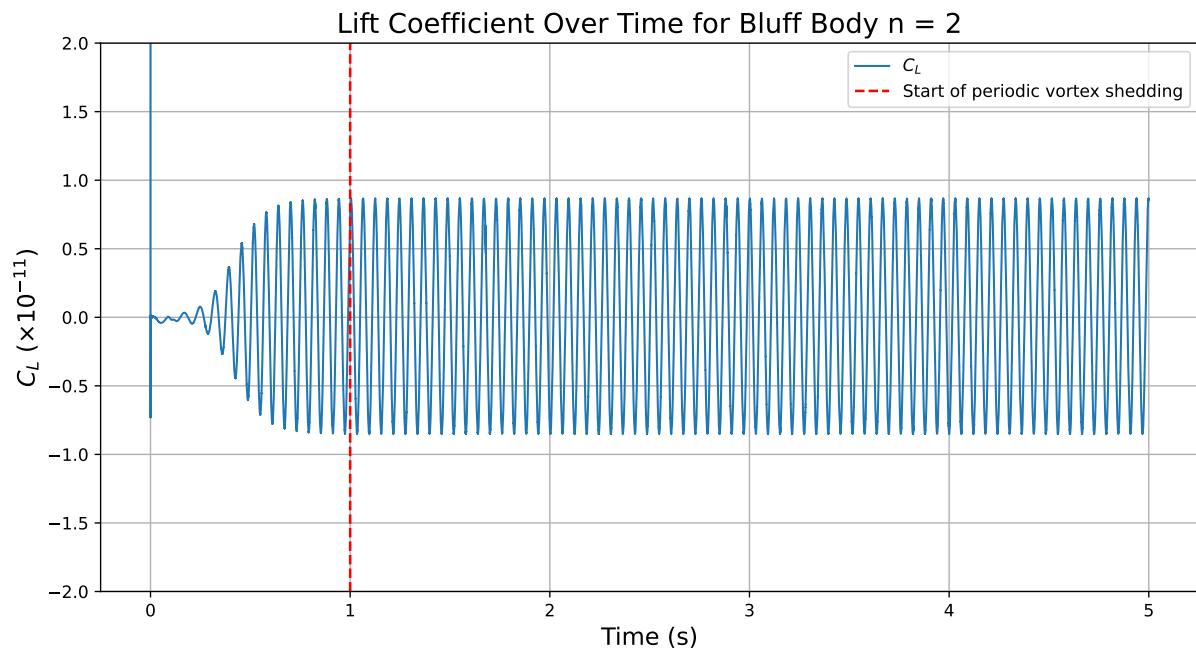

Figure 13: Lift coefficient C_L over time for the bluff body $n = 2$. The red dashed line indicates the start of periodic vortex shedding at $t = 1$ s.

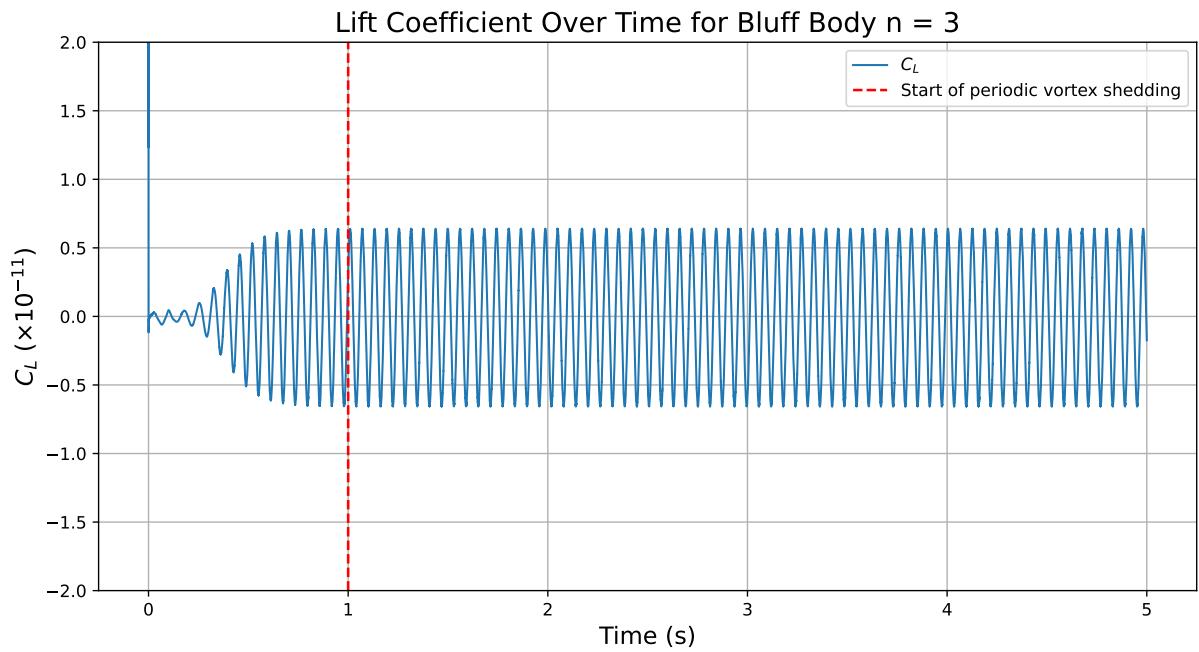

Figure 14: Lift coefficient C_L over time for the bluff body $n = 3$. The red dashed line indicates the start of periodic vortex shedding at $t = 1$ s.

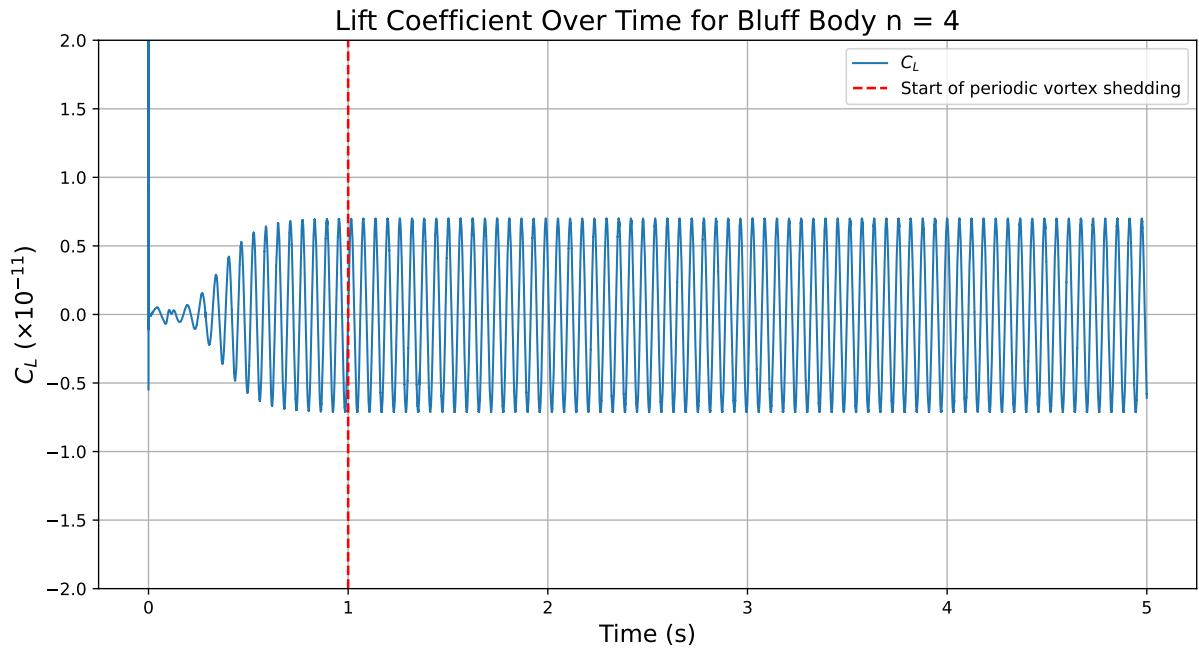

Figure 15: Lift coefficient C_L over time for the bluff body $n = 4$. The red dashed line indicates the start of periodic vortex shedding at $t = 1$ s.

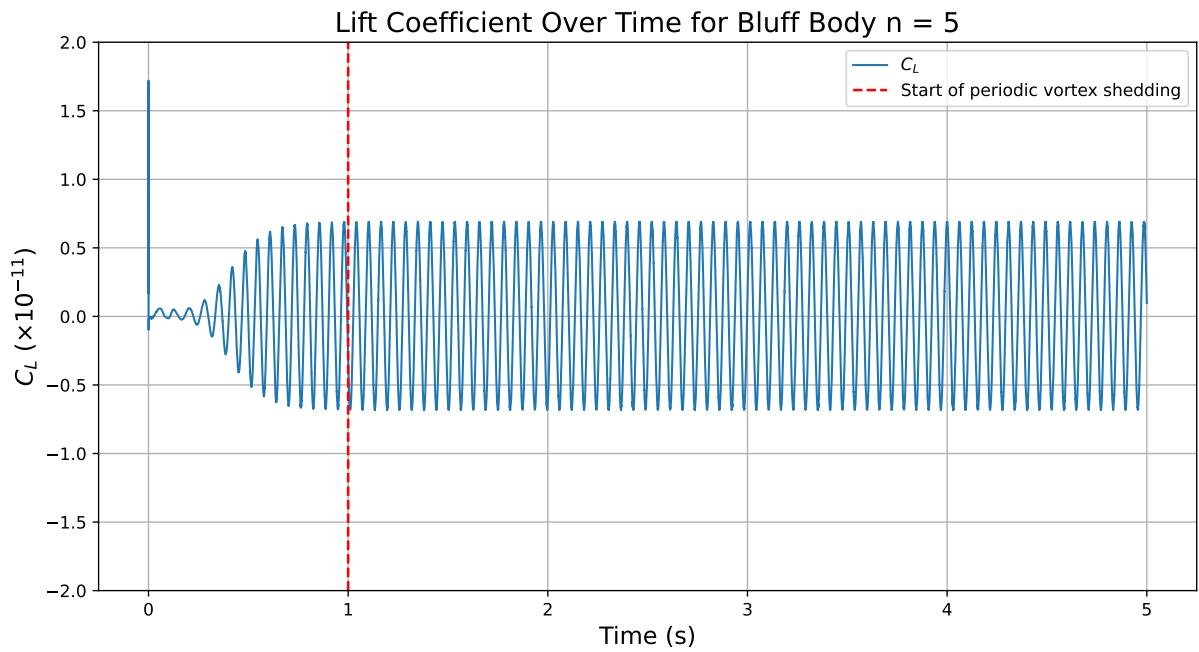

Figure 16: Lift coefficient C_L over time for the bluff body $n = 5$. The red dashed line indicates the start of periodic vortex shedding at $t = 1$ s.

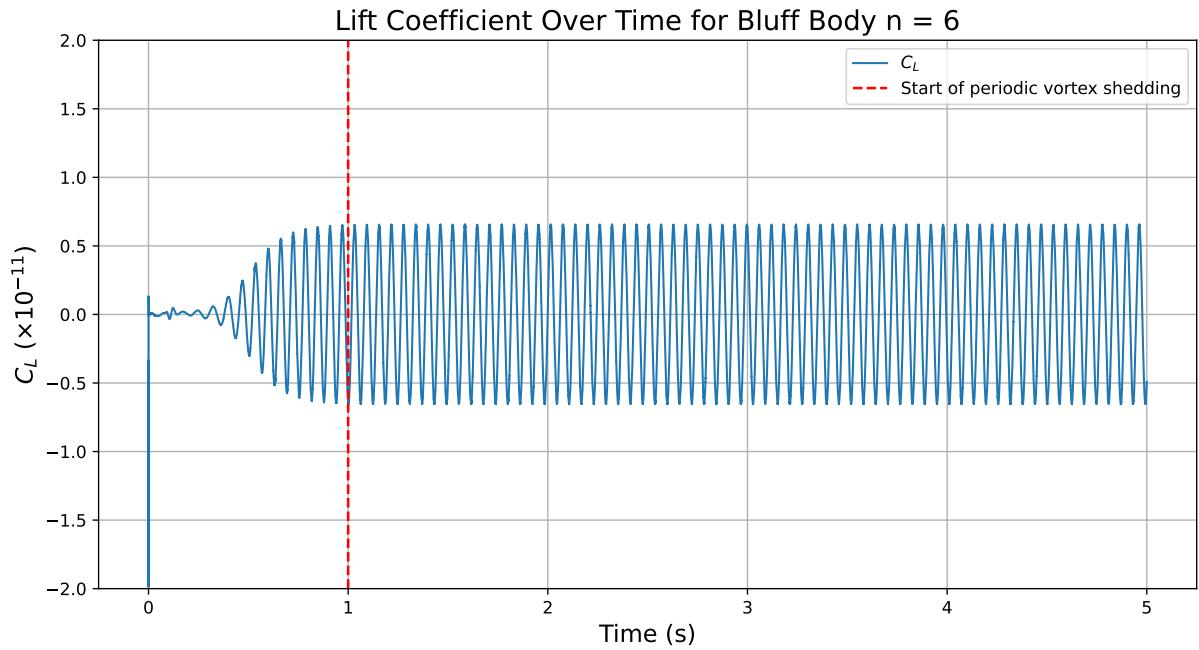

Figure 17: Lift coefficient C_L over time for the bluff body $n = 6$. The red dashed line indicates the start of periodic vortex shedding at $t = 1$ s.

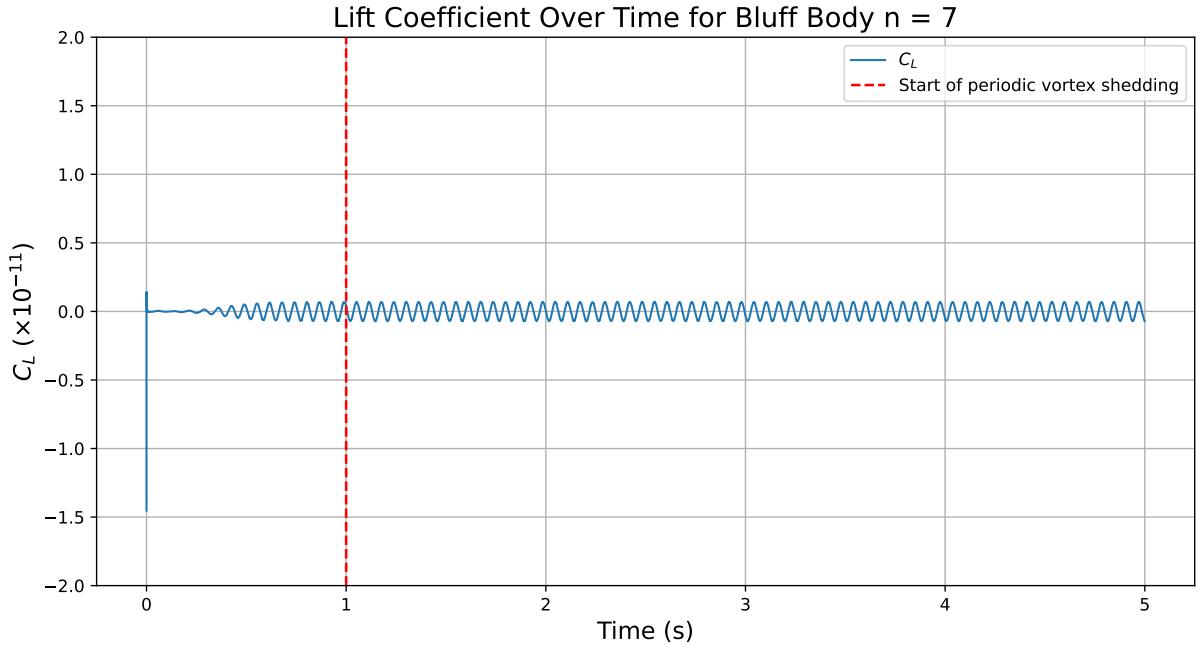

Figure 18: Lift coefficient C_L over time for the bluff body $n = 7$. The red dashed line indicates the start of periodic vortex shedding at $t = 1$ s.

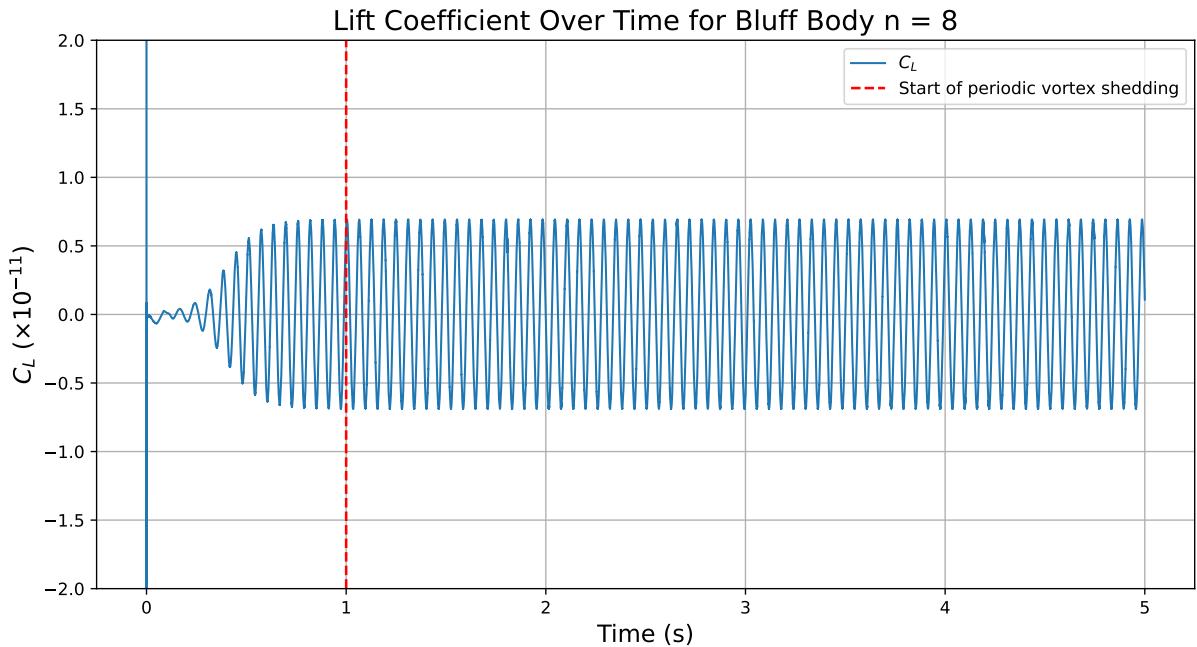

Figure 19: Lift coefficient C_L over time for the bluff body $n = 8$. The red dashed line indicates the start of periodic vortex shedding at $t = 1$ s.

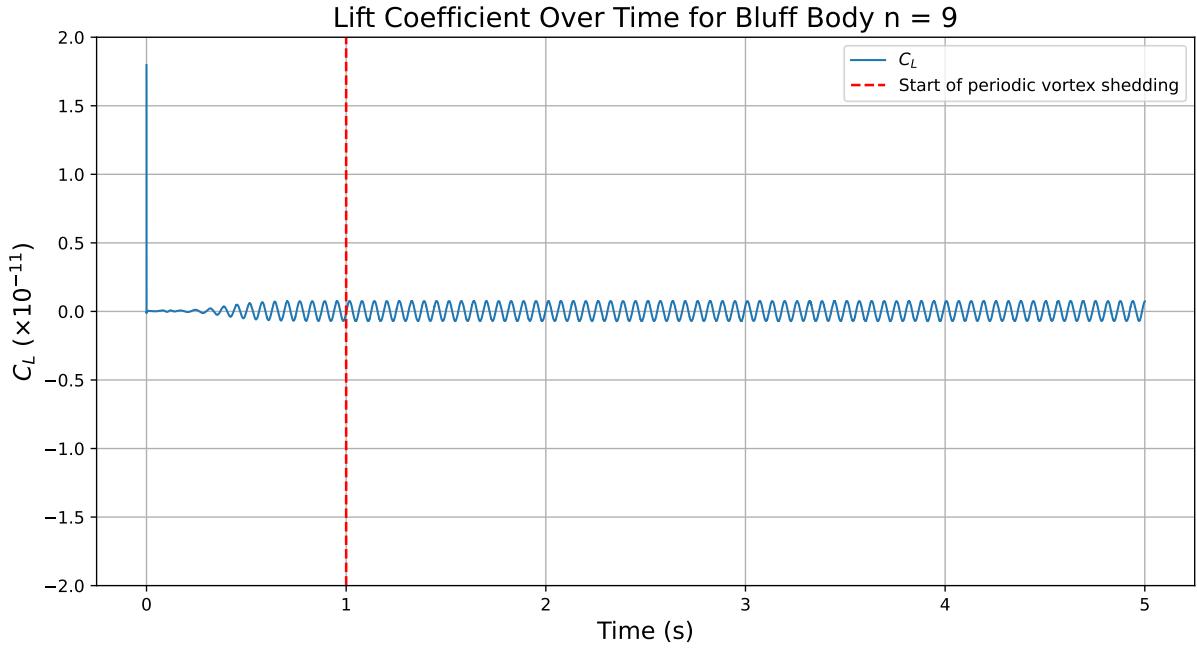

Figure 20: Lift coefficient C_L over time for the bluff body $n = 9$. The red dashed line indicates the start of periodic vortex shedding at $t = 1$ s.

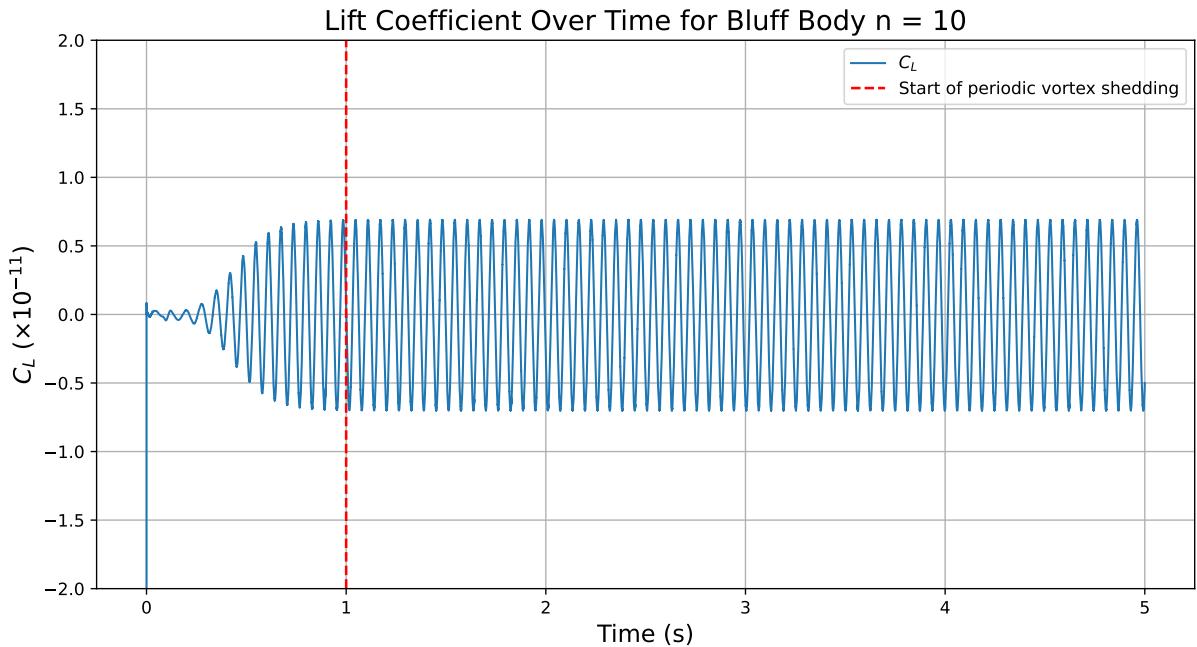

Figure 21: Lift coefficient C_L over time for the bluff body $n = 10$. The red dashed line indicates the start of periodic vortex shedding at $t = 1$ s.

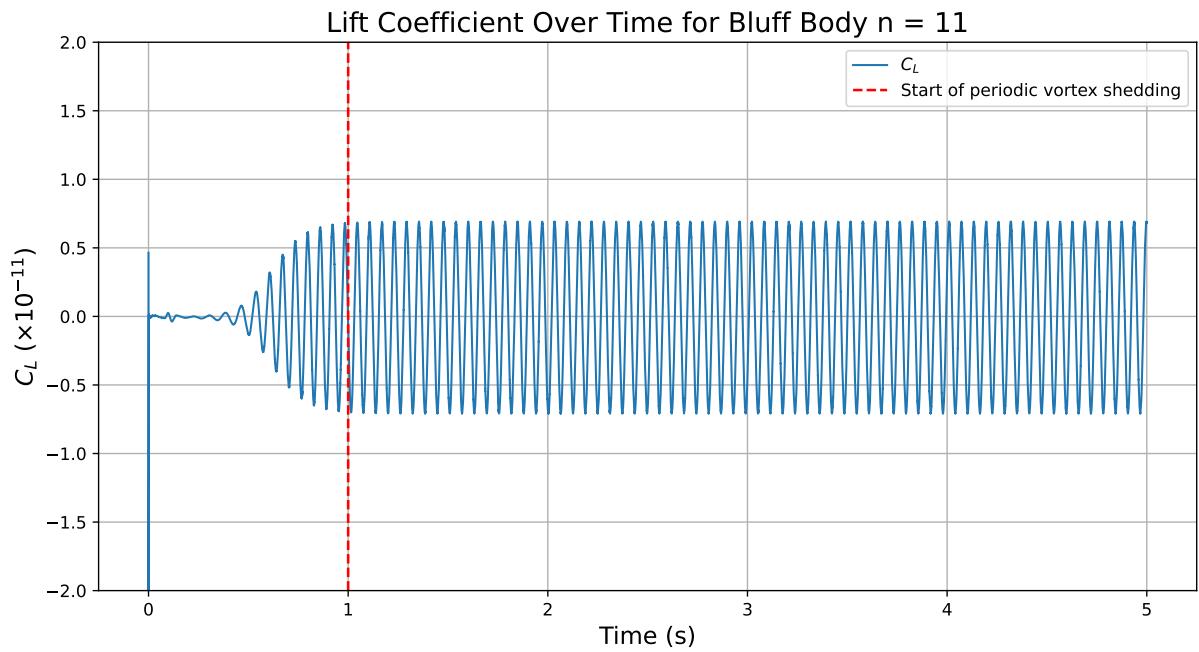

Figure 22: Lift coefficient C_L over time for the bluff body $n = 11$. The red dashed line indicates the start of periodic vortex shedding at $t = 1$ s.

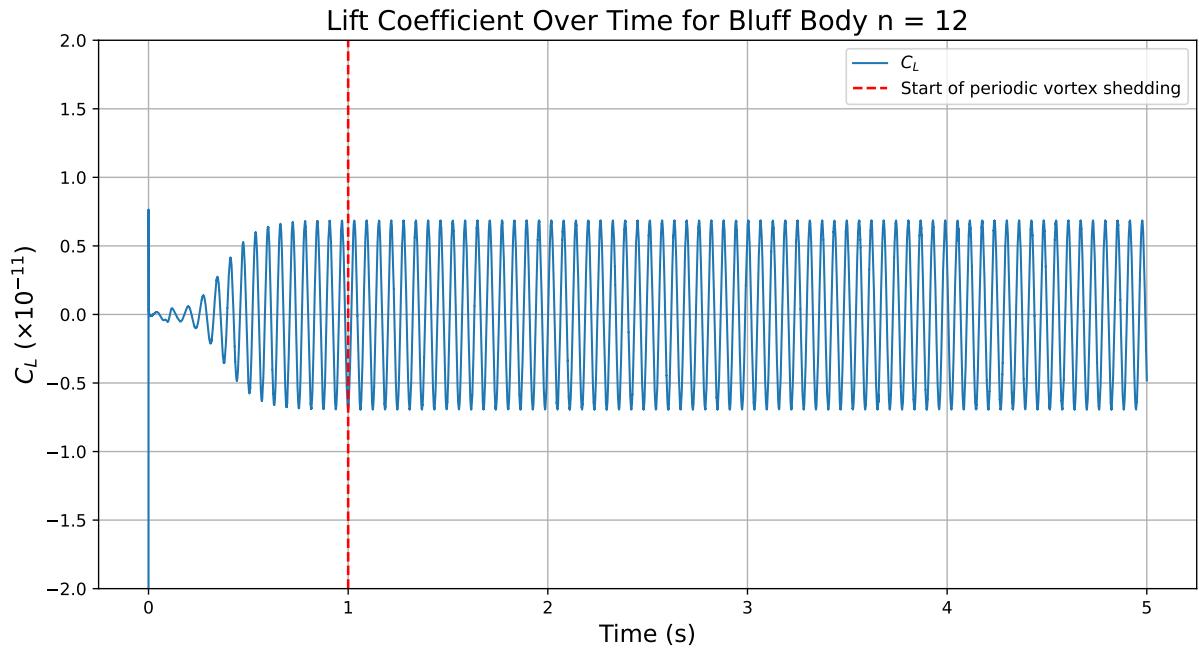

Figure 23: Lift coefficient C_L over time for the bluff body $n = 12$. The red dashed line indicates the start of periodic vortex shedding at $t = 1$ s.

6.1.3 Sample Calculation of Vortex Shedding Frequency for Bluff Body $n = 2$ using Python

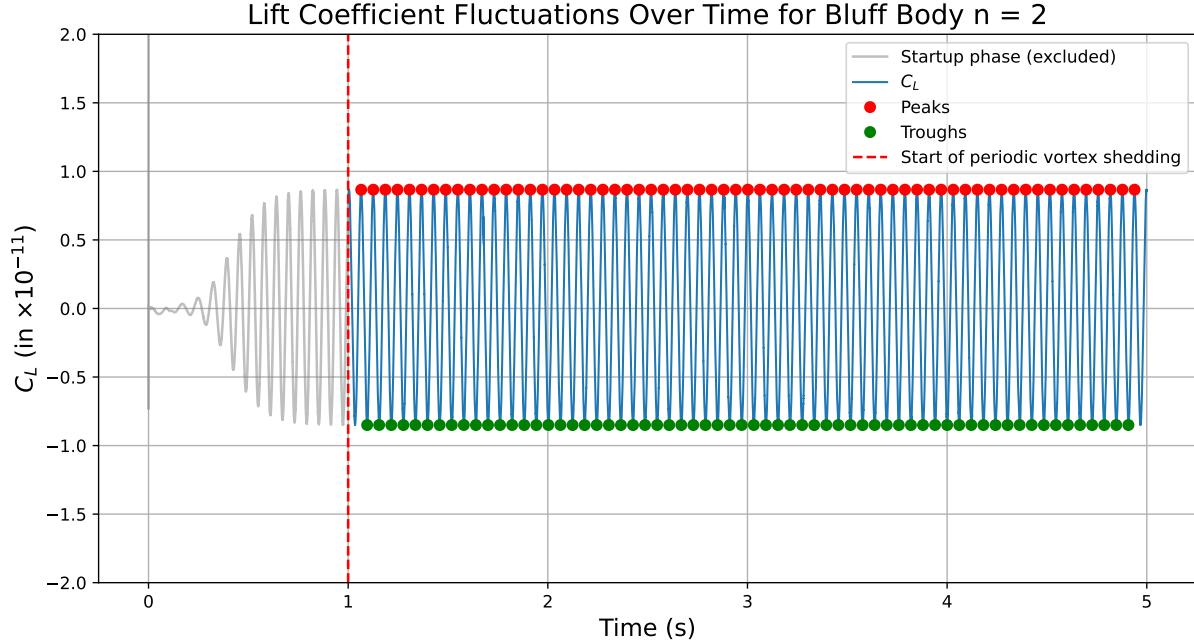

Figure 24: Sample visualization of the peaks and troughs identification on the Lift Coefficient C_L over time graph for bluff body $n = 2$. The initial startup phase, colored in gray, is excluded from the detection.

Python Output

```
Number of peaks: 65
Number of troughs: 64

Average time period: 0.06052 s
```

Using the outputted average period $T = 0.06052$ s, the vortex shedding frequency was calculated:

$$f = \frac{1}{T} = \frac{1}{0.06052} = 16.52346 \text{ Hz}$$

This represents the vortex shedding frequency of the bluff body with $n = 2$ faces in laminar flow.

6.1.4 A Comparison of Vortex Shedding Frequency with Increasing n from 2 – 12

Bluff Body n	Vortex Shedding Frequency (Hz)
2	16.52346
3	16.36393
4	16.41497
5	16.22323
6	16.28664
7	16.07976
8	16.32387
9	16.05910
10	16.09528
11	16.18909
12	16.21797

Table 5: Vortex shedding frequencies for bluff bodies with n streamwise faces.

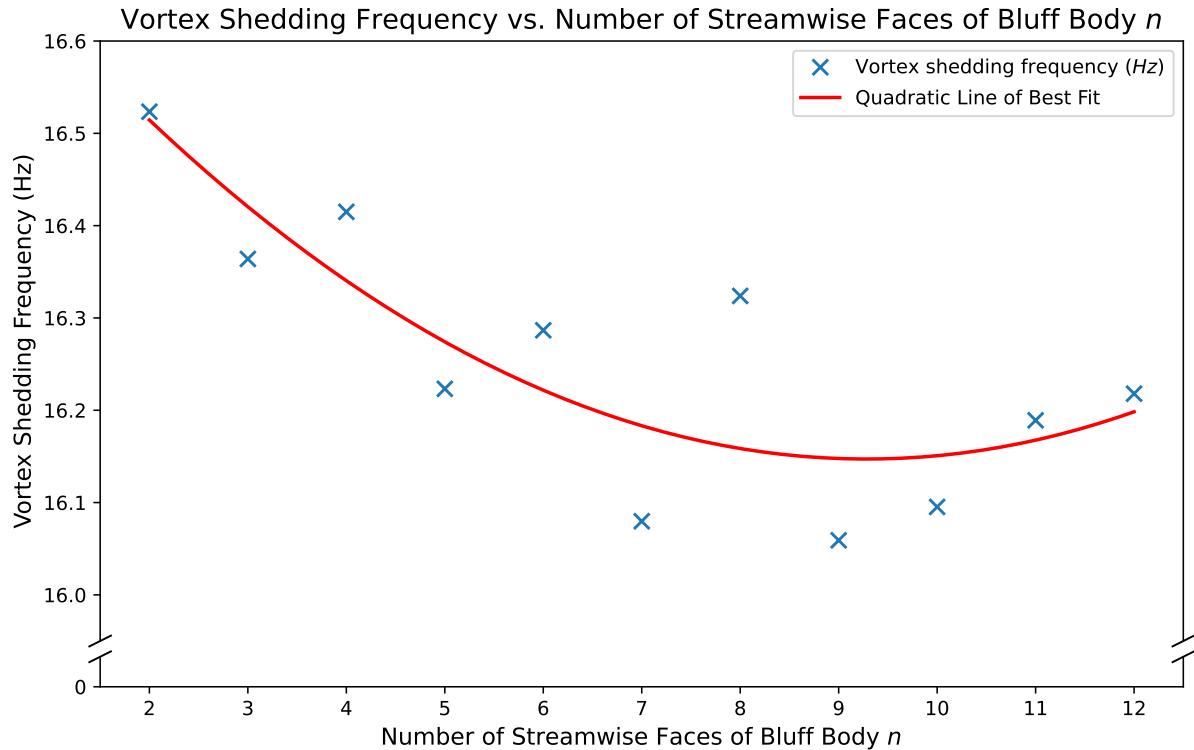

Figure 25: A comparison of vortex shedding frequency with increasing n from 2 – 12

In order to better visualize the general non-linear trend a quadratic line of best fit was included.

6.2 Results of Practical Investigation

The found average flow velocity was 0.04 m s^{-1} . Despite many attempts to achieve laminar flow, the flow remained turbulent, as demonstrated by the irregular wake patterns and a calculated Reynolds number of 800 — determined using Equation (2) where $U = 0.04 \text{ m s}^{-1}$, $\nu = 1 \times 10^6 \text{ m}^2 \text{ s}^{-1}$, and $L = 0.02 \text{ m}$. Nevertheless, the practical experiment yielded qualitative value.

7 Conclusion

The goal of this study was to investigate how the number of streamwise faces n of a bluff body influence the vortex shedding frequency in laminar flow. Bluff bodies ranging from $n = 2 - 12$ were analyzed both theoretically and practically. However, only the theoretical investigation yielded quantitative results.

The research question was thoroughly explored by theoretical means using OpenFOAM simulations, allowing for precise measurements of the fluctuations of the lift coefficient, and therefore an accurate determination of the vortex shedding frequency. Although the practical component of this investigation failed to achieve laminar flow conditions, it provided beneficial visual insight into the mechanism of vortex shedding, enhancing the investigation's tangibility while aiding conceptual understanding.

It was found that there is an overall decrease in vortex shedding frequency as the number of streamwise faces n of a bluff body increases — confirming the previously mentioned hypothesis. This trend is exemplified by bluff body $n = 2$ which produced a vortex shedding frequency of 16.523 46 Hz, while the bluff body $n = 12$ produced a vortex shedding frequency of 16.217 97 Hz. The overall trend is in agreement with literature such as Gonçalves and Del Rio Vieira (1999) which concluded that a higher number of streamwise faces leads to a decreased Strouhal number and therefore a decreased vortex shedding frequency. However, the effect of bluff body geometry on vortex shedding frequency has only been examined for a limited selection of shapes, leaving countless configurations, including many of those investigated in this study, previously unexplored (Przulj, 1998, p. 22).

The measured values from $n = 2 - 7$ follow a fluctuating pattern with periodic increases and decreases. Bluff bodies with an even number of streamwise faces n tend to exhibit a greater vortex shedding frequency than their preceding odd-number counterparts, though conclusively claiming this would require further investigation.

Bluff body $n = 8$ seems to be an anomaly with a vortex shedding frequency of 16.323 87 Hz. Although this is lower than the vortex shedding frequency of bluff body $n = 2$, therefore confirming the overall trend, its vortex shedding frequency is higher than that of bluff body $n = 6$.

Bluff body $n = 9$ exhibits a significantly smaller decrease (only 0.020 66 Hz) in vortex shedding frequency to bluff body $n = 7$, possibly indicating a shift away from the previous overall downtrend. When considering bluff bodies $n = 9 - 12$, one identifies a positive correlation between the vortex shedding frequency and the number of streamwise faces n , contrary to the previous downtrend. It seems that as the leading edge becomes more circular, the vortex shedding frequency tends to increase. Further investigation would be required to confirm this claim.

A quadratic line of best fit produced an R^2 value of 0.6977, indicating a moderate non-linear correlation between the number of streamwise faces n and the vortex shedding frequency. The rather low R^2 value coupled with the anomaly of bluff body $n = 8$ may be attributed to numerical uncertainties of the simulation (Przulj, 1998). The anomalously low amplitudes of fluctuations of lift coefficient for bluff bodies $n = 7$ and $n = 9$ provide further evidence of possible numerical uncertainties.

8 Evaluation

8.1 Evaluation of the Theoretical Investigation

The simulation used for the theoretical investigation was based off of a tutorial case made by a professional, with minor changes made in order to adhere to the aim of this essay. As detailed in Section 5.4.1, the simulation was run five times for each bluff body, yielding identical results for each repetition and therefore providing a strong foundation for the results of this investigation. Unlike the practical investigation, the simulation provided a method of study in which a two-dimensional flow could be investigated without the impact of boundary walls. Moreover, the simulated environment enabled strict control over the constant variables, thereby minimizing the influence of confounding factors, ensuring the alteration of vortex shedding frequency could be solely attributed to the change in the number of streamwise faces.

The measurement of the lift coefficient C_L was done within the simulation, eliminating the uncertainties introduced by external measurement equipment. Furthermore, the determination of the time period was completed for all peaks and troughs, with an average providing the final time period, therefore reducing the impact of anomalies on the results.

Nevertheless, as mentioned in Section 7, numerical uncertainties introduced by numerous factors such as the mesh resolution may remain a reason for error, especially due to the difficult nature of quantifying these potentially mutually canceling factors (Przulj, 1998). Computational limitations restricted both the unit size of the mesh of the domain and the time step value (Δt), therefore possibly introducing discrepancies between the modeled and actual fluid behavior.

This was partially solved by the inclusion of a BOI, decreasing the unit size of the mesh around the bluff body and in the wake region. Coupled with a decreased unit size at the edge of the bluff body, the interaction of the bluff body with the flow was simulated more accurately.

8.2 Evaluation of the Practical Investigation

The inability to achieve laminar flow rendered the practical investigation nonviable for quantitative comparison with simulated data. It would have been necessary to decrease the characteristic length of the bluff bodies, the flow velocity or a combination of both. However, as discussed earlier in Section 5.3, decreasing the size of the bluff bodies would have resulted in smaller vortices, too small to identify by eyesight. In addition, the lack of a less powerful water pump rendered a further decrease in flow velocity — beyond that provided by the regulation valve — unachievable.

Even if a Reynolds number of 100 had been achieved, the presence of the horizontal plate and the surrounding insulation foam walls would have slowed the flow near the surface boundaries, causing boundary layer formation, disrupting the uniform flow. It is fundamentally unfeasible to achieve a truly two-dimensional flow in a three-dimensional physical space — therefore any data would have only served as approximations.

Additionally, there is an inherent difficulty in identifying the exact point when a vortex is shed through visual inspection. In combination with possible human error, when using the digital stop watch, any data collected would have lacked accuracy.
